ABSTRACT

A study of the influence of citric acid (CA) addition by a post-treatment method during the preparation of a series of Mo/Al₂O₃ catalysts on the thiophene HDS activity was conducted. The Mo/Al₂O₃ catalysts were also prepared by a chemical vapor deposition (CVD) technique using Co(NO₃)₂NO to introduce Co atom and characterized by means of NO adsorption, XRD, Mo K-edge EXAFS and XRF. With 8.7 wt% Mo, citric acid was not affected very much for the Co-Mo/Al₂O₃ catalysts. On the other hand, an outstanding result was shown that the HDS activity was drastically enhanced by 5 times up to Mo content around of 25 wt% Mo. It is suggested that the post treatment increased the dispersion of MoS₂ particles, in particular at a high Mo loading. This was also supported by the amount of NO adsorption and amount of Co anchored by the CVD results, which enhanced as the increasing Mo loading up to 25 wt% Mo. Moreover, Mo-CA complex species were observed on the post-treatment method and CVD technique was one of advanced method to prepare Co-Mo-S phases selectively.

Keywords: preparation, citric acid, post-treatment, hydrodesulfurization, CVD

INTRODUCTION

Development of highly active hydrodesulfurization (HDS) catalysts is still needed not only for obtaining zero sulfur emission and zero sulfur fuel in the future, but also to efficiently utilize limited natural resources. Supported nickel- or cobalt-molybdenum sulfide catalysts are widely used in the industrial HDS process [1]. It is now well recognized that the active sites of the HDS catalysts are the so-called Co(Ni)-Mo-S phase, in which Co(Ni) decorates the edge sites of highly dispersed MoS₂ particles [1]. Therefore, many improvements of HDS catalysts preparation have been proposed in order to get a greater amount of active sites, Co-Mo-S phases, as well as better knowledge of the structure of catalytically active phase, support-active phase interaction and new activation procedure. One simple and effective method to boost catalytic activity is with the use of chelating agent in the catalysts preparation [2], for instance citric acid (CA).

In the catalyst preparations, chelating agents are usually added by the simultaneous impregnation method, including citric acid. It has been reportedly that with using citric acid with the simultaneous-impregnation method, better performance of the HDS catalytic activity is obtained [2]. Moreover, the dispersion of MoS₂ particles and the degree of sulfidation of Mo oxide precursors are also improving [2-3]. Similar result is also observed on our previous result when citric acid was added by the simultaneous impregnation method in the catalyst preparation [4]. However, information about the detail roles of citric acid is still unclear. In the present study, other preparation method of addition of citric acid was conducted. Citric acid was impregnated on the calcined Co-Mo/Al₂O₃ catalysts, as called a post-treatment method here. We studied the influence of citric acid to the performance on the HDS reaction of thiophene related with a series content of Mo and CA, and characterized them by a variety of physicochemical techniques. A chemical vapor deposition (CVD) technique with Co(NO₃)₂NO as the probe molecule was used to introduce Co atom on the sulfide Mo/Al₂O₃. By CVD, all of the Co atoms were preferentially anchored on vacant MoS₂ edge sites, resulting in the full occupation of the edges of the MoS₂ particles with Co atoms [5-7]. Hence, the maximum potential activity of Co-Mo catalysts can be estimated [6-7].

EXPERIMENTAL SECTION

Materials

The commercial standard of γ-Al₂O₃ (JRC-ALO-7) was supplied by the catalysts society of Japan. Ammonium heptamolybdate (NH₄)₆Mo₇O₂₄·4H₂O, citric acid (C₆H₈O₇), thiophene (C₇H₈S) and cobalt carbonyl (Co(CO)₅NO) were used in here as analytical grade.
Moreover, all gases (He, H₂, 10% NO/He and 10% \( \text{H}_2\text{S}/\text{H}_2 \)) were used as a high purity quality.

**Instrumentation**

On-line gas chromatography (GC), X-ray fluorescence (XRF), X-ray diffraction (XRD), and Mo K-edge X-ray Absorption Fine Structure (XAFS) were apparatus that used in the present study.

**Procedure**

**Catalysts Preparation**

A series of MoO₃/Al₂O₃ was prepared by an impregnation technique. \( \gamma \text{Al}_2\text{O}_3 \) (SSA: 180 m²g⁻¹) was impregnated with an \( \text{NH}_4\text{MoO}_4\cdot4\text{H}_2\text{O} \) (AHM) aqueous solution, followed by calcination at 773 K for 5 h. The Mo content of Mo/Al was 8.7-35 wt% Mo. Then, the calcined Mo/Al was impregnated with a citric acid (CA) aqueous solution (CA/Mo mole ratio = 2); this step was followed by just drying at 383 K for 16 h (without calcination). This catalyst preparation technique is denoted here as a post-treatment method. Another series, the CA/Mo mole ratio was varied up to 2 with 8.7 and 20 wt% Mo/Al₂O₃ catalysts were also prepared by the post-treatment method. The pH of the impregnation solution was not adjusted in the present study.

The prepared catalysts were sulfided in a 10% \( \text{H}_2\text{S}/\text{H}_2 \) flow at 673 K for 1.5 h. The sulfidation procedures have been described previously [4]. A chemical vapor deposition (CVD) technique using \( \text{Co(CO)}_3\text{NO} \) as a precursor was applied to introduce Co into the sulfided Mo/Al₂O₃ catalyst [4-7]. Briefly, the sulfided catalyst was first evacuated at 673 K for 1 h and subsequently exposed for 5 min at room temperature to a vapor of \( \text{Co(CO)}_3\text{NO} \) kept at 273 K. After 10 min evacuation at room temperature, the sample was sulfided again at 673 K for 1.5 h. The catalyst thus prepared is denoted as Co-Mo/Al₂O₃. The amount of Co incorporated by the CVD technique was determined for the sulfided catalysts by means of XRF analysis (Shimadzu, EDX-700HS). The accuracy of the Co content was within ± 5%.

**Reaction Procedure**

The initial activity of the freshly prepared catalyst was evaluated on the HDS reaction under mild conditions using a circulation system made of glass (batch system). The catalyst (about 0.1 g) sulfided in-situ was evacuated at 673 K for 1 h before the catalytic reaction. The HDS of thiophene was carried out at 623 K and the initial \( \text{H}_2 \) pressure of 20 kPa. The thiophene pressure was kept constant (2.6 kPa) during the reaction [4-5]. The reaction products were analyzed by on-line gas chromatography. The products were mainly C₄ compounds such as n-butane, 1-butene, and cis-trans-2-butene and a corresponding amount of \( \text{H}_2\text{S} \). The output products were periodically monitored during the reaction. The HDS activity was calculated on the basis of the accumulated amount of \( \text{H}_2\text{S} \) evolved after 1 h reaction divided by the catalyst weight. The amounts of \( \text{H}_2\text{S} \) evolved from the sulfided catalysts were estimated by blank experiments without introduction of thiophene vapor into the reactor, showing that they were negligibly small [less than (5-10) \times 10⁻⁵ mol h⁻¹ g⁻¹] compared with the amount of \( \text{H}_2\text{S} \) formed by the HDS reaction. The reproducibility of the HDS activity test was better than ± 4%.

**Characterizations**

The amount of NO adsorption on the sulfide Mo/Al₂O₃ catalyst prepared by citric acid addition was measured by a pulse technique. After cooling in the \( \text{H}_2\text{S}/\text{H}_2 \) stream, the sulfided catalyst (0.1 g) was flushed at room temperature with a high purity He stream (20 cm³ min⁻¹). A pulse of 5.0 cm³ of 10% NO/He (purity of NO > 99%, atmospheric pressure) was repeatedly injected every 8 min to the He stream by using a six-way stopcock until no adsorption was detected (pulse size; 20 µmol NO/pulse, 10-15 pulses). The effluent gas was analyzed by a gas chromatograph equipped with a thermal conductivity detector to measure the amount of NO. The amount of NO adsorption was calculated from the cumulative amount of NO adsorption. The reproducibility was usually within ± 5% of the total amount of NO adsorption [5,8].

Moreover, X-ray diffraction (XRD) measurements were carried out on a Miniflex II Desktop X-ray Diffraction apparatus (Rigaku) with 30 kV and 15 mA, equipped with an automatic divergence slit. The radiation source was Cu Kα₁ (λ = 1.541841 Å) with a Ni filter. Mo K-edge X-ray Absorption Fine Structure (XAFS) spectra were measured for oxidic Mo/Al₂O₃ with or without the citric acid addition and for reference compounds in a transmission mode at room temperature at NW-10A in the PF-AR (Photon Factory-Advanced Ring for pulse X-Rays) of the Institute of Material Structure Science, High Energy Accelerator Research Organization (KEK-IMSS-PF-AR) with 6.5 GeV ring energy and 100-50 mA stored current (proposal No. 2006G331, 2008G200). The synchrotron radiation was monochromatized by a Si (311) double crystal monochromator. The EXAFS data were analyzed by assuming a spherical wave approximation and a single scattering model. The EXAFS data were Fourier-transformed from k-space (40-150 nm⁻¹) to R-space. The empirical backscattering amplitude and phase shift for Mo-Mo pairs were extracted from EXAFS data for polycrystalline MoS₂.
RESULT AND DISCUSSION

Catalytic Activity

Fig. 1 shows the catalytic activity of the Mo/Al₂O₃ catalysts for the HDS of thiophene as a function of CA/Mo mole ratio. The HDS activity of the 8.7 wt% Mo/Al₂O₃ catalysts was slightly decreased by the addition of citric acid using post-treatment method up to CA/Mo mole ratio = 1 and was leveled off by a further addition of citric acid. With the 20wt% Mo/Al₂O₃ catalysts, the HDS activity was significantly increased when citric acid was added by the post-treatment method up to a CA/Mo mole ratio around 1 and became constant at CA/Mo > 1. It is noteworthy in Fig. 1 that the effect of citric acid addition strongly depends on the Mo loading and that the HDS activity of 20 wt% Mo/Al₂O₃ is significantly increased by the post-treatment with citric acid at CA/Mo mole ratio > 1.

Fig. 2 depicts the HDS activity of a series of Mo/Al₂O₃ catalyst as a function of Mo loading without the citric acid addition. The HDS activity of calcined Mo/Al₂O₃ catalysts was gradually decrease as the Mo loading was increased, suggesting that the dispersion area of MoS₂ particles was not enough on the Al₂O₃ surface (3-3.2 Mo nm²) and the bulky MoO₃ crystalline became created, in agreement with our previous result [6]. However, on the post-treated Mo/Al₂O₃ catalysts, the HDS activity was enhance 2 times even at higher Mo loading (Mo ≤ 25 wt%). It seems that the dispersion of MoS₂ particles was enhanced with the addition of citric acid. It is suggested that together with citric acid, perhaps, MoO₃ crystalline rendered the Mo-CA complex structures and become well dispersed on the support.

Moreover, the CVD technique was applied to get deeper insight into the different behaviors of these catalysts in Fig. 2 [7]. The HDS activity of calcined Co-Mo/Al₂O₃ catalysts was sharply decrease with increasing Mo loading, explaining that the dispersion of MoS₂ particles become decreased as a high Mo loading. Surprisingly, Fig. 2 shows that the HDS activity was drastically increase even at higher Mo loading (up to 25 wt% Mo) which almost reach 5 times compare with the calcined catalysts before the CVD. It means that a great amount of active sites, Co-Mo-S phases, was formed because of the formation of highly dispersed of MoS₂ particles on the support when citric acid was added by the post-treatment. It is noteworthy that a post-treatment method with citric acid is effective to improve the performance activity of HDS catalyst.

Dispersion of Mo prepared by citric acid

The amount of Co anchored by the CVD process was evaluated by XRF analysis. The amounts of Co in Co-Mo/Al₂O₃ with/out the citric acid addition are depicted in Fig. 3 as a function of Mo content. Obviously, the amount of Co on the calcined Co-Mo/Al₂O₃ was decreased as the Mo content was increased, indicating that the edge dispersion of MoS₂ particles become decreased with the increasing of Mo content. On the other hand, the amount of Co on the post-treated Co-Mo/Al₂O₃ catalysts significantly increased up to Mo content around of 25 wt% Mo. It seems that the MoS₂ particles are still highly dispersed on the support Al₂O₃ even at a high Mo loading by the post-treatment with citric acid.

Similar trend result is also observed on the NO adsorption capacity shown in Fig. 4. With the post-treatment, the NO adsorption capacity is still increased even at a high Mo loading (Mo ≤ 25 wt%), while it is not
observed on the calcined Mo/Al₂O₃ catalysts. The amounts of NO adsorption (Fig. 4) and Co incorporation (Fig. 3) clearly show that the post-treatment of the calcined Mo/Al catalysts with citric acid greatly increases the dispersion of MoS₂ particles and, correspondingly, the amount of active sites, Co-Mo-S. Moreover, interesting point is shown at the 8.7 wt% Mo content in Fig. 4. The amount of NO adsorption was not changed after the citric acid was added. It considers that Mo has already well dispersed forming monolayer on the surface support [6], in consistent with the result in Fig. 2.

Fig. 5 shows that MoO₃ diffraction peaks were clearly observed for the calcined 20 wt% Mo/Al catalyst together with the peaks due to γ-Al₂O₃. The diffraction peaks due to crystalline MoO₃ were removed when citric acid was used by the post-treatment (Fig. 5-b) and became broadened peaks. It is considered that citric acid consumes the crystalline MoO₃ particles to form Mo-CA complexes and Mo becomes well-dispersed or in an amorphous form on the surface Al₂O₃. Meanwhile, the XRD patterns of the calcined Mo/Al catalyst with 8.7 wt% Mo showed no MoO₃ diffraction peaks with or without the addition of citric acid by the post-treatment, indicating that Mo is already well-dispersed on the support forming monolayer at 8.7 wt% Mo [6].

Mo K-edge XAFS measurements were conducted in order to get information on the local structure of Mo species. Fig. 6 shows the Mo K-edge XAFS Fourier transforms (FT) for oxidic Mo/Al₂O₃ prepared by the post-treatment method using citric acid (CA/Mo = 2.0). This present study only used the Mo-Mo region to discriminate these Mo species due to the Mo-O region 0.08–0.20 nm is not well resolved for differentiation of Mo species. And thus, only the Mo-Mo region 0.23–0.40 nm was analyzed to characterize Mo species in the Mo/Al₂O₃ catalysts. The Mo-Mo structural parameters, as assessed from the XAFS analyses for the oxide catalysts, are listed in Table 1. As shown in Table 1, the Mo-Mo atomic distance for the 8.7 wt% Mo/Al₂O₃ catalysts was 0.33 nm after calcination, indicating that molybdenum is present mainly as polymolybdate-like species (Fig. 6A). The Mo-Mo atomic distance was increased to 0.34 nm and became close to that for the Mo-CA complex, when citric acid was added by the post-treatment method, showing that Mo-CA complexes are formed even at a CA/Mo mole ratio of 1.2, in consistent with Fig. 1. However, the Mo-Mo coordination number of the catalysts was lower than that for the reference compound as listed in Table 1, suggesting a structural disorder of Mo-CA complexes due to the interaction with the support surface and/or a partial formation of the complexes. Nevertheless, the
Table 1. Structural parameters* derived from Mo K-edge EXAFS for Mo/Al oxide catalysts prepared by using citric acid (CA/Mo mole ratio = 1.2).

presence of a Mo-CA monomeric complex is not excluded for these catalysts.

With the 20 wt% Mo/Al₂O₃ catalysts shown in Fig. 6B, the Mo-Mo atomic distance for the calcined catalyst was 0.37 nm. It is clearly shown that molybdenum is present predominantly as MoO₃ species on the calcined catalyst, in conformity with the XRD results shown in Fig. 5. When citric acid was used in the preparation, the Mo-Mo atomic distance became 0.34 nm by the post-treatment. The local structure of Mo in 20 wt% Mo/Al₂O₃-post-treated shows the formation of Mo-CA surface complexes. However, the Mo-Mo coordination number of the Mo-CA surface complexes (0.3) was considerably lower than that of the reference compound (Table 1), suggesting that the Mo-CA complexes on 20 wt% Mo/Al₂O₃ catalysts are in structural disorder and/or are partially formed. We conclude from the characterizations by XRD and XAFS that citric acid consumes crystalline MoO₃ particles and, probably, coexisting well-dispersed Mo oxide clusters to form highly dispersed Mo-CA surface complexes and, in part, polymolybdate species by the post-treatment of calcined Mo/Al with citric acid. The Mo K-edge XANES spectra for these catalysts (not shown for brevity) are consistent with this conclusion.

Effect of post-treatment on Mo/Al₂O₃ catalyst

Fig. 2 clearly shows that the HDS activity of 8.7 wt% Mo/Al₂O₃ and Co-Mo/Al₂O₃ is not changed or even decreased with the addition of citric acid by the post-treatment method. The amounts of NO adsorption (Fig. 3) demonstrate that the dispersion of MoS₂ particles is unchanged or even decreased after citric acid was added. Therefore, we conclude that with the 8.7 wt% Mo/Al₂O₃ catalyst system the addition of citric acid does
not affect the catalyst properties very much or is even detrimental, since in the present Mo/Al₂O₃-calcined catalyst a monolayer dispersion of Mo is established and Mo oxides are extremely highly dispersed on the support at 8.7 wt% Mo [1,6,9]. Yet, Mo K-edge XAFS (Fig. 6A) clearly show that Mo-CA complexes are formed by the addition of citric acid. We consider that the Mo-CA complex formation weakens the support-Mo precursor interactions and thus results in a slight decrease of the dispersion of MoS₂ particles.

Moreover, the present study demonstrates that the HDS activities of 20 wt% Mo/Al₂O₃ and Co-Mo/Al₂O₃ are significantly increased after citric acid was added by the post-treatment method (Fig. 2). Figs. 3 and 4 clearly show that the dispersion of MoS₂ particles is greatly increased by the post-treatment at a high Mo content (up to 25 wt% Mo). It is revealed by XRD (Fig. 5) and the Mo K-edge XAFS (Fig. 6 and Table 1) that, in the case of the post-treatment, citric acid consumes crystalline MoO₃ particles and, probably, coexisting well-dispersed Mo oxide clusters to form well-dispersed Mo-CA surface complexes. The present study demonstrates that the addition of citric acid by the post-treatment is very effective to increase the edge dispersion of MoS₂ particles on the catalysts, in particular, at a high Mo content (up to 25 wt% Mo).

We also propose that other favorable effects of citric acid addition on the 20 wt% Co-Mo/Al₂O₃ catalysts causes weakened interactions between Mo and the support surface due to the formation of Mo-CA surface complexes as well as the increased dispersion of Mo precursors at the expense of crystalline MoO₃ particles. Therefore, facilitating easy sulfidation of Mo and thus improving the sulfidation degree of Mo on the Mo/Al₂O₃ catalysts by the post-treatment method, in particular at high Mo loading (20 wt% Mo). This agrees with the observations by Funamoto and Segawa [3] and by Fujikawa et al. [10].

Moreover, in order to estimate the adsorption sites of Co(CO)₅NO on MoS₂, we made a correlation between the Co/Mo mole ratio for Co-Mo/Al₂O₃ by the CVD and the NO/Mo mole ratio for Mo/Al₂O₃ as depicted in Fig. 7. It is shown that a good proportional correlation in Fig. 7 for these catalysts, demonstrating that the Co atoms introduced to Mo/Al₂O₃ by the CVD was selectively decorated on the edge sites of MoS₂ particles to form active sites, Co-Mo-S phases, since it is well established [1] that NO molecules absorb on coordinatively unsaturated Mo sites on the edge sites of MoS₂ particles [5]. However, it is also shown in Fig. 7 that the Co/Mo ratio for the post-treatment catalysts at 8.7 wt% Mo was slightly higher than the value expected from the liner line, describing an excess amount of Co over that requires for full decoration on MoS₂ edges sites is anchored on 8.7 wt% Mo/Al₂O₃-post-treatment. It is suggested that Co atom was also adsorbed on the Al₂O₃. With 8.7 wt% Mo, a monolayer dispersion of MoS₂ particles (3-3.2 Mo nm⁻²) was already formed on the support. Therefore, the addition of citric acid just modified the interaction between support and Mo precursor and the textural properties of Al₂O₃. Thus, some of Co atoms is also anchored with the surface Al₂O₃ together with citric acid. Moreover, it is worth to be noted that the CVD technique is one of advanced method for the HDS catalyst preparation to prepare active sites selectively, Co-Mo-S, without the formation of Co sulfide clusters, Co₉S₈ [5-7].

CONCLUSION

Based on the HDS activity and the physicochemical data, it is concluded that the HDS activity and the edge dispersion of MoS₂ particles are not modified very much by the post-treatment method with citric acid at 8.7 wt% Mo loading due to already monolayer dispersion. On the other hand, significantly improvement of the HDS activity and the edge dispersion of MoS₂ particles are observed at a high Mo content (up to 25 wt% Mo) by the post-treatment. It is indicated that citric acid consumes crystalline MoO₃ particles on the calcined MoO₃/Al₂O₃ by the post-treatment method to form well-dispersed Mo-CA surface complexes and thus improves the edge dispersion of MoS₂ particles on the catalyst surface after sulfidation. Moreover, it is suggested that the sulfidation degree of Mo for Mo/Al₂O₃ catalysts is also increased with citric acid addition by the post-treatment in particular, at a high Mo content. A CVD technique is
one of advance method for the HDS catalysts preparation to form Co-Mo-S phases selectively without the formation of Co sulfide clusters.

ACKNOWLEDGEMENT

I express my thanks to Prof. Y. Okamoto for his discussion, advices, and support during this work, also Dr. T. Kubota for the Mo K-edges XFAS measurements of the catalysts.
